Abstract—We show that the widely used homotopy method for solving fixed-point problems, as well as the Harsanyi-Selten equilibrium selection process for games, are PSPACE-complete to implement. Extending our result for the Harsanyi-Selten process, we show that several other homotopy-based algorithms for finding equilibria of games are also PSPACE-complete to implement. A further application of our techniques yields the result that it is PSPACE-complete to compute any of the equilibria that could be found via the classical Lemke-Howson algorithm, a complexity-theoretic strengthening of the result in [24]. These results show that our techniques can be widely applied and suggest that the PSPACE-completeness of implementing homotopy methods is a general principle.

Keywords—game theory, computational complexity

1. INTRODUCTION

According to Roger Myerson [20], the 1950 publication of Nash’s paper on equilibria was a watershed event not just for Game Theory, but for Economics in general. The new general equilibrium concept, and its established universality, was an impetus for understanding rationality in much more general economic contexts, and inspired the important price equilibrium results by Arrow and Debreu. Myerson argues convincingly in [20] that the concept of Nash equilibrium lies at the foundations of modern economic thought.

Seen from an algorithmic perspective, however, the Nash equilibrium suffers from two important problems: First, it is not clear how to find it efficiently (the same is true for the Arrow-Debreu variety for markets and prices). This shortcoming had already been identified by economists since the 1950s, and much effort has been devoted to algorithms for finding Nash equilibria, see [25, 19, 14] for examples from a very extensive literature. None of these algorithms came with polynomial-time guarantees, however, and the recent result [6, 4] establishing that the problem is PPAD-complete explains why. Of the many algorithmic approaches proposed by economists over the past 50 years for finding Nash equilibria, most have been shown by now to require exponential time in the worst case [24, 16]. One exception is an important algorithmic genre known as homotopy methods [7]; see [15] for a recent survey.

In topology, a homotopy is a continuous transformation from one function to another (as, for example, between two paths joining two points on a map). The homotopy method starts with a fixed-point problem that is easy to solve (say, a rotation of a disc around its center), and continuously transforms it into the problem in hand, by “pivoting” to new fixed points along the way. A theorem by Browder [2] establishes the validity of this method in the limit, by showing the existence of a continuous path of fixed points that joins two fixed points of the initial and the final problems.

The second algorithmic obstacle for the Nash equilibrium concept is multiplicity. Games have multiple equilibria, and markets many price equilibria, and thus the corresponding equilibrium concepts are only nondeterministic predictions (oxymoron intended). In price equilibria, this multiplicity has been blamed for economic crises: The path guaranteed by Browder’s theorem is non-monotonic, going back and forth in time. As a result, equilibria vanish at its folds, leaving the market in turmoil [1]. In games, a proposed remedy for multiplicity is the so-called focal point theory see, e.g., [18] p. 414, postulating that players implicitly coordinate their equilibrium choice by focusing on the most obvious, or mutually advantageous, equilibrium; repeated play and learning (see, e.g., [9]) can also be considered a remedy for multiplicity. In 1975, Harsanyi proposed the tracing procedure [10] for battling equilibrium multiplicity, a theory further explicated in his joint 1988 book “A General Theory of Equilibrium Selection in Games” with Selten [11] (Harsanyi and Selten shared in 1994 the Nobel prize with Nash). The tracing procedure asserts that players engaged in a game $G$ play at first a simple game $G_0$, in which their prior beliefs about the other players’ behavior result in a dominant strategy. As time $t$ progresses, and their priors are falsified by life, they play a more and more realistic game $G_t = (1 - t) \cdot G_0 + t \cdot G$, until, at time $t = 1$, they end up playing the intended game $G$. They show that, for almost all games, tracing the equilibrium path of this process results in a unique equilibrium. Notice the parallel with the homotopy method; apparently the two were discovered independently.

Our results: This paper is a complexity-theoretic critique of the tracing procedure and the homotopy method: we show that finding the solutions they prescribe requires the power of PSPACE. In particular, finding the Browder fixedpoint that would have been
discovered by the homotopy method, for a simple starting point and an adversarial final one, is PSPACE-complete. The same is true, via standard reductions, for price equilibria. We also construct examples where the homotopy method not only will undergo an exponential number of pivots (this was expected since [16]), but will suffer an exponential number of direction reversals. As for the tracing procedure, we show that it is PSPACE-complete to find the Nash equilibrium selected by it, even in two-player games, and even if the initial game has dominant strategies obtained from priors, exactly as prescribed by Harsanyi and Selten. We extend this result to homotopy-based algorithms where the starting game depends on the final game and show that it is PSPACE-complete to implement the Herings-van den Elzen, Herings-Peeters, and van den Elzen-Talman algorithms for finding equilibria in games. Finally, it is particularly noteworthy that PSPACE-completeness prevails even for finding the solutions that would be returned by the classical Lemke-Howson algorithm, a simplex-like method that had long been considered an oasis of conceptual simplicity and (until [24]) of algorithmic hope in this field. This reinforces the “exponentially long paths” result of [24] with a new result which says that, subject only to the hardness of PSPACE, no short cuts to Lemke-Howson solutions are possible (for any of the different initial choices of the algorithm). Since it is known that the Lemke-Howson algorithm can be expressed as a homotopy [15], this result can also be seen as a powerful specialization of our first result.

The algorithms we consider solve problems in the complexity class PPAD, which is contained in TFNP, the class of all total function problems in NP. Another prominent complexity class contained in TFNP is PLS (for polynomial local search). Many common problems in PLS (e.g., local max cut and finding pure equilibria of congestion games) are complete under a so-called tight PLS-reduction, implying that the corresponding standard local search algorithm is exponential (for certain starting configurations and any choices of the local search algorithm). Furthermore, one can conclude that the computational problem of finding a local optimum reachable from a given starting configuration by local search is PSPACE-complete.

No such concept of tight reductions is known for PPAD, and our results can be seen as addressing this deficiency. Specifically, we show the PSPACE-completeness (and exponential worst-case behaviour) of a number of homotopy-based algorithms for finding equilibria. Our reductions start with the problem OTHER END OF THIS LINE (OEOTL), which is related to the problem END OF THE LINE used in the definition is PPAD, seeking not just any end of a path, but the other end of the particular path starting at the origin. OEOTL was known to be PSPACE-complete since [23], but this fact has so far remained unexploited for proving lower bounds for other problems.

Outline of the paper: In Section 2.1, we give an overview of the linear homotopy method as applied to Brouwer functions and games. In Section 2.2, we recall the PSPACE-complete problem OEOTL (OTHER END OF THIS LINE), which serves as the starting point for all our main reductions. In Section 3, we show that the linear homotopy method to compute a Brouwer fixpoint is PSPACE-complete, which is proved in Section 3.3. In Section 4, we establish the PSPACE-completeness of the linear tracing procedure for two-player strategic form games for a special starting game that is independent of the final game. These results are extended to starting games that depend on the final game in Section 5, where we show that it is PSPACE-complete to implement the Herings-van den Elzen, Herings-Peeters, and van den Elzen-Talman algorithms for computing equilibria of games. The techniques of [4, 6] are central to both Section 3 and Section 4 and are recalled and extended along the way. Finally, in Section 6, we show that it is PSPACE-complete to find any solution of a two-player game by the Lemke-Howson algorithm.

2. Preliminaries

2.1. Homotopies

A Brouwer function $F$ is a continuous function from a convex and compact domain $D$ to itself; by Brouwer’s fixpoint theorem there exists $x \in D$ such that $F(x) = x$. A homotopy between two functions $F_0 : X \to Y$ and $F_1 : X \to Y$ (where $X$ and $Y$ are topological spaces) is a continuous function $H : [0,1] \times X \to Y$ such that for all $x \in X$, $H(0,x) = F_0(x)$ and $H(1,x) = F_1(x)$. In this paper, we are interested in the special case where $X = Y = D$, for $D$ a closed compact subset of Euclidean space, such as a cube. Thus, $F_0$ and $F_1$ are Brouwer functions on $D$. Given two continuous functions $F_0, F_1 : D \to D$, the linear homotopy is given by the expression $H(t,x) = (1-t)F_0(x) + tF_1(x)$, and (if $D$ is convex) results in a continuum of Brouwer functions $F_t : D \to D$ given by $F_t = (1-t)F_0 + tF_1$ for $t \in [0,1]$.

Brouwer’s fixpoint theorem [2] (not to be confused with Brouwer’s fixpoint theorem) asserts that given a homotopy connecting $F_0$ and $F_1$, there is a path in $[0,1] \times D$ from some fixpoint of $F_0$ to some fixpoint of $F_1$ such that for every point $(t,x)$ on that path, $x$ is a fixpoint of $F_t$. The homotopy method [7, 15] for finding a fixpoint of $F_1$ selects $F_0$ to have a unique and easy to find fixpoint, and essentially follows such a path. As noted in [15], we do not expect the path to be monotonic in $t$—indeed, we show in the full paper that an exponential number of direction reversals is possible.

We are often interested in approximate fixpoints. If $F$ is a Brouwer function, an $\epsilon$-approximate fixpoint is a point $x$ such that $|F(x) - x| \leq \epsilon$ (we shall use the $L_\infty$ metric throughout). It follows from Brouwer’s theorem that, for any $F_0, F_1$, there is a finite sequence $x_0, x_1, \ldots, x_k, x_1$ of $\epsilon$-approximate fixpoints of $F_0, F_1, \ldots, F_k, F_1$, for some $k$ and $t_1, \ldots, t_k$, such

1A very interesting alternative consideration [8] focuses on exact fixpoints, resulting in higher complexity of the search problem; here we could also consider exact fixpoints and equilibria without much effect on our results, since we are dealing with PSPACE-completeness. It is known from [8] that this harder problem belongs to PSPACE.
that any two consecutive fixpoints in the sequence are at most $\epsilon$ apart.

We shall be interested in the following problem, which we call BROWDER FIXPOINT: Given two arithmetic circuits computing two functions $F_0$ and $F_1$ from $[0,1]^n$ to itself with Lipschitz constant $\ell$, an $\epsilon > 0$, where $F_0$ has a unique fixpoint $x_0$, find an $\epsilon$-approximate fixpoint $x_1$ of $F_1$ that is connected via a sequence of $\epsilon$-approximate fixpoints to $x_0$. (To make this definition precise, we of course have to identify classes of functions from which $F_0$ and $F_1$ may be drawn.) Notice that the homotopy method for computing Brouwer fixpoints provides a solution to this problem.

Homotopies can be defined very similarly also for games. Given two games $G_0,G_1$ of the same type (number of players and strategies), we consider $G_t = (1-t)\cdot G_0 + t\cdot G_1$, where it is the players’ utilities that are interpolated. It is routine to extend this definition to more general classes of games, such as graphical games [17] (in which case, in addition to the players and strategies, the two graphs must be the same). Browder’s theorem, via Nash’s reduction, establishes that there is a path of approximate Nash equilibria here as well. The problem LINEAR TRACING is the following: Given two games $G_0$ and $G_1$, an $\epsilon > 0$, and a Nash equilibrium $x_0$ of $G_0$, find an $\epsilon$-approximate Nash equilibrium $x_1$ of $G_1$ that is connected via a sequence of $\epsilon$-approximate Nash equilibria to $x_0$.

It is easy to see that LINEAR TRACING is in PSPACE, and it can be checked that the algorithm of Herings and van den Elzen [13] achieves this. BROWDER FIXPOINT is also in PSPACE.

2.2. OTHER END OF THIS LINE

We consider directed graphs on $2^n$ vertices represented as $n$-bit vectors. The arcs are represented by two polynomial-size circuits $S$ and $P$, each having $n$ inputs and outputs, as follows. There is an arc from vertex $v$ to $w$ provided that $S(v) = w$ and $P(w) = v$. Notice that all vertices of the graph have both indegree and outdegree 0 or 1, that is, the graph consists of paths, cycles, and isolated vertices.

Definition 1: An $(S,P)$ graph with parameter $n$ is a graph on $\{0,1\}^n$ specified by circuits $S$ and $P$, as described above, subject to the constraint that vertex 0 is has no incoming arc but does have an outgoing arc.

The problem END OF THE LINE is the problem of finding a vertex of a given $(S,P)$ graph other than 0 that has at most one incident arc. Note that this problem is in the class TFNP of total search problems in NP: there exists a solution that could be obtained by following the directed path that starts at 0, and any given solution may be efficiently checked for correctness. The class PPAD [23] is defined as all search problems polynomial-time reducible to END OF THE LINE. The problem OTHER END OF THIS LINE (which we will subsequently abbreviate to OEOTL) is the problem of finding the end of the particular path that starts at 0. In contrast with END OF THE LINE, a given solution to an instance of OEOTL has no obvious concise certificate that it is the correct endpoint, so while OEOTL is a total search problem, it is apparently not an NP total search problem. In fact, we have the following (Theorem 2 of [23]), which is the starting-point of our reductions.

Theorem 1: [23] OEOTL is PSPACE-complete.

We build on the ideas of [6, 4] (showing that unrestricted Nash equilibria can efficiently encode END OF THE LINE solutions) to show how equilibria defined by homotopies can efficiently encode OEOTL solutions.

3. THE HOMOTOPY METHOD FOR BROWWER FIXPOINTS

In this section we give detailed definitions of classes of fixpoint and approximate fixpoint computation problems. In Section 3.1, we review the definition of Brouwer-mapping functions—and related concepts—from Chen et al. [4], here applied to a three dimensional domain. In Section 3.2, we review the techniques of [6, 4] for implementing Brouwer-mapping functions as arithmetic circuits. In Section 3.3, we prove Theorem 3, the main result of Section 3, in which we establish the PSPACE-completeness of a linear homotopy for finding a fixpoint of a Brouwer function. $n \in \mathbb{N}$ will denote a complexity parameter of problem instances. We define a sequence $F_0(n)$ of “basic Brouwer functions” having unique known fixpoints. For each $n$ we define a class of Brouwer functions whose members encodes $(S,P)$-graphs on $\{0,1\}^n$. The homotopy of Equation (1) defines a class of functions $F_t$, $t \in [0,1]$, that interpolate between $F_0$ and $F_1$ and specifies a particular fixpoint of $F_1$. We will show that from that fixpoint, we can efficiently recover a solution to OEOTL for the graph encoded by $F_1$. 

3.1. Definitions and notation

Notation 1: Let $K$ be the unit 3-D cube $[0,1]^3$. For $n \in \mathbb{N}$ let $K^{(n)}$ denote a partition of $K$ into $2^{3n}$ “cublets”, $K^{(n)} = \{K_{ijk} : 0 \leq i,j,k \leq 2^n - 1\}$; $K_{ijk}$ is an axis-aligned cube of length $2^{-n}$ whose vertex closest to the origin has coordinates $2^{-n}(i,j,k)$.

We define a Brouwer-mapping circuit in a similar way to the definition in [4], here specialized to the case of 3 dimensions. We also introduce some variations of the definition, as follows:

Definition 2: A Brouwer-mapping circuit (bmc) is a directed boolean circuit with 3n input nodes and 2 output nodes. Note that any bmc $B$ has an associated Brouwer-mapping function (bmf) $f_B : K^{(n)} \rightarrow \{0,1,2,3\}$ that maps any cublet $K_{ijk}$ to one of the four colors $\{0,1,2,3\}$. We require the colors of all exterior cublets to be predetermined as follows. For $i = 0$, $f_B(K_{ijk}) = 1$. For $j = 0$, $i > 0$, $f_B(K_{ijk}) = 2$. For $k = 0$, $i,j > 0$, $f_B(K_{ijk}) = 3$. All other exterior cublets are mapped to 0.

The basic bmc $f_0^{(n)} : K^{(n)} \rightarrow \{0,1,2,3\}$ has the additional property that all internal cublets get mapped to 0. Notice that $f_0^{(n)}$ is computable by a bmc of size polynomial in n.
A DGP-style bmf is one that is derived from an \((S, P)\)-graph in the manner of \([6]\), and so is computable with a bmc of size polynomial in the size of circuits \(S\) and \(P\). (Proposition 1 notes the relevant property of DGP-style bmf’s.)

A partial bmf \(f\) is defined with respect to a set \(S \subseteq \mathcal{K}^{(n)}\); \(f\) assigns a color to elements of \(S\) but \(f\) may be undefined on non-elements of \(S\).

**Proposition 1:** The following problem is PSPACE-complete. Given a Brouwer-mapping circuit \(B\), find a point in \(K\) that is a vertex of 4 cubelets mapped to all 4 colors by the associated bmf \(f_B\), and which is connected to the origin via cubelets having colors other than 0.

This is a total search problem: the topological intuition is that there is a line that is adjacent to the colors \(1, 2, 3\) and has one end at \(2^{-\alpha}(1, 1, 0)\). The other end must be inside \(K\) and adjacent to color 0, since no other exterior point is adjacent to the colors \(1, 2, 3\).

The proof of Proposition 1 in the full paper, applies the reduction of \([6]\) from END OF THE LINE to the version of the problem where a panchromatic vertex is sought that is adjacent to all colors. The resulting \(1, 2, 3\)-colored line has a structure that faithfully simulates the arcs of the \((S, P)\)-graph from which is was derived. Panchromatic vertices correspond to END OF THE LINE solutions, and are linked-up with the \(1, 2, 3\)-colored line, whose structure corresponds to the END OF THE LINE graph, and whose orientation arises from the clockwise order of \(1, 2, 3\) around it.

### 3.2. Implementing Brouwer-mapping functions as arithmetic circuits

We review a class of functions used to establish PPAD-completeness of graphical and strategic-form games. Recall that \(K\) denotes the 3-dimensional unit cube; we consider continuous functions \(F : K \to K\) having the following structure. Each function is an arithmetic circuit composed of nodes, with each node taking inputs from up to 2 other nodes, and producing an output, for example, the sum of its inputs. All values are constrained to \([0, 1]\), so a node that adds its inputs would output 1 if their sum is greater than 1. Identify 3 nodes as “input nodes” and another 3 as “output nodes”, so if \(F\) is a function from \(K\) to \(K\), it has a Brouwer fixpoint.

**Definition 3:** A linear arithmetic circuit is an arithmetic circuit that computes a function from \(K\) to \(K\), represented by a directed graph whose nodes are “gates” that perform certain basic arithmetic operations on their inputs as follows. Each gate takes as input 0, 1 or 2 real values in \([0, 1]\) and outputs a single real value in \([0, 1]\), where the output of a gate may be the sum/difference/max/min of two inputs, or a constant multiple of a single input, or no input and constant output. (An output value is set to 1 if for example two inputs that sum to more than 1 are input to a “sum” gate.) We also allow “comparator gates” in which the output of such a gate evaluates to 1 (respectively, 0) if its first input is greater (respectively, less) than the second input, and may take any value if they are equal.

**Notation 2:** Let \(\alpha = 2^{-2^{n}}\). Let \(\delta_1 = (\alpha, 0, 0)\), \(\delta_2 = (0, \alpha, 0)\), \(\delta_3 = (0, 0, \alpha)\), \(\delta_4 = (-\alpha, -\alpha, -\alpha)\).

**Definition 4:** We shall say that a Brouwer-mapping function \(f\) is implemented by an arithmetic circuit \(C\) if whenever \(f(K_{ijk}) = c\), then \(C(x) - x = \delta_c\) when \(x\) is at the center of \(K_{ijk}\). For \(x\) not at a center, \(C(x - x)\) should be a convex combination of values of \(C(z) - z\) for cubelet centers \(z\) within \(L_{\infty}\) distance \(2^{-n}\) of \(x\). Given \(F : K \to K\) computed by such a \(C\), we shall similarly say that \(F\) implements \(f\).

**Observation 1:** If \(F\) implements \(f\), then any fixpoints of \(F\) must lie within distance \(2^{-n}\) of panchromatic vertices of \(f\), and vice versa.

**Theorem 2:** A Brouwer-mapping function having complexity parameter \(n\) can be implemented using a linear arithmetic circuit having \(\text{poly}(n)\) gates, that computes a continuous function.

The proof gives a new technique to implement any Brouwer-mapping function \(f\) as a continuous function \(F\) that uses a linear arithmetic circuit. This is in contrast with the corresponding techniques of \([4, 6]\) that used a sampling-based approach in order to smooth the transition between distinct cubelets. The sampling-based approach results in discontinuous functions, where Brouder’s theorem would not be applicable (although it could still be applied to a continuous approximation). The technique only works in constant dimension; if can be extended to higher dimension using the “snake-embeddings” of \([4]\).

**Proof:** Let \(f : \mathcal{K}^{(n)} \to \{0, 1, 2, 3\}\) be a Brouwer-mapping function. We construct a continuous Brouwer function \(F : K \to K\) computed by a linear arithmetic circuit \(C\) as follows.

For \(x\) at the center of cubelet \(K_{ijk}\), set \(F(x) - x = \delta_c\) where \(c = f(K_{ijk})\). For \(x\) a vertex of cubelets \(K_{c} \in \mathcal{K}^{(n)}\), set \(F(x) - x\) to be the average of \(F(z) - z\) for all points \(z\) at the centers of members of \(K_{c}\). The relevant points \(z\) can be obtained using a polynomial-sized piece of circuitry.

Let \(S\) be a simplicial decomposition of the unit cube consisting of 12 simplices that share a vertex at the center of the cube, and all other vertices are vertices of the cube. Let \(S_{ijk}\) be the simplicial decomposition of cubelet \(K_{ijk}\) obtained by scaling \(S\) down to \(K_{ijk}\). Applied to all cubelets in \(\mathcal{K}^{(n)}\) this results in a highly regular decomposition \(S^{(n)}\) of \(K\) into \(12 \cdot 2^{2n}\) simplices.

For any \(x \in K\), \(F(x)\) is obtained by linearly interpolating between the vertices of the simplex in \(S^{(n)}\) that contains \(x\). Clearly \(F\) is continuous.

The result follows from the following claim:

**Proposition 2:** \(F\) as defined above, may be computed by a linear arithmetic circuit of size polynomial in \(n\).

**Proof:** If \(x\) is not a vertex of \(S^{(n)}\), the circuit can determine the vertices of a simplex \(S_x \in S^{(n)}\) that contains \(x\). There may be more than one such simplex, in which case it does not matter which is chosen.

The circuit has 12 cases to consider, depending on the orientation of \(S_x\). Each case can be handled in the same general manner, by subtracting some vertex \(v\) of \(S_x\) from \(x\), and multiplying \((x - v)\) by some
constants (the coefficients of the linear function that interpolated between the vertices of $S_\epsilon$). Note that we never need to multiply two computed quantities together, multiplication only ever takes place between a computed quantity and a constant, as required for a linear arithmetic circuit.

3.3. The PSPACE reduction to linear arithmetic circuits

In this subsection, we establish the PSPACE-completeness of the problem BROWDER FIXPOINT, mentioned in the Introduction, which can now be made precise as follows. We use two bmfs $f_0$ and $f_1$, where $f_0$ is the basic bmf of Definition 2, and $f_1$ shall be a DGP-style bmf that encodes an instance of END OF THE LINE as constructed in [6]. Let $\mathcal{F}_0$ and $\mathcal{F}_1$ be implementations of $f_0$ and $f_1$ using linear arithmetic circuits as described in the proof of Theorem 2. For $\mathcal{F}: K \rightarrow K$ let $\mathcal{F}^{(i)}$ denote the $i$-th component of $\mathcal{F}$. For $i = 1, 2, 3$ let

$$
\begin{align*}
\mathcal{F}_0^{(i)} &= (\mathcal{F}_0^{(i)} - t) + (\mathcal{F}_0^{(i)} - (1 - t)) \\
\mathcal{F}_1^{(i)} &= \max(\min(\mathcal{F}_0^{(i)}, \mathcal{F}_1^{(i)}), \mathcal{F}_0^{(i)})
\end{align*}
$$

where in (1), the outputs of operators $+$ and $-$ are restricted to lie in $[0, 1]$ (so, rounding to 0 or 1 if needed). $\mathcal{F}_0$ interpolates continuously between $\mathcal{F}_0$ and $\mathcal{F}_1$ and is constructed from them using elements of the linear arithmetic circuits of Definition 3 (which is useful later; the natural alternative $\mathcal{F}_0 = t \mathcal{F}_0 + (1 - t) \mathcal{F}_1$ does not have this property.)

Observation 2: For all $t \in [0, 1]$, $\mathcal{F}_0^{(i)}$ is Lipschitz continuous, with Lipschitz value $< 2^{2^{-n}}$.

$\mathcal{F}_0$ has a unique fixpoint close to $2^{-n}(1, 1, 1)$. $\mathcal{F}_0$ is a “basic Brouwer function” which forms the starting-point of homotopies we consider. Hence Observation 2 and Browder’s fixpoint theorem implicitly define a corresponding fixpoint of $\mathcal{F}_1$.

Define an approximate fixpoint of $\mathcal{F}: K \rightarrow K$ to be a point $x \in K$ with $|\mathcal{F}(x) - x| \leq \alpha / 5$ (recall $\alpha = 2^{-2^n}$).

Theorem 3: It is PSPACE-complete to find, within accuracy $2^{-n}$, the coordinates of the fixpoint of $\mathcal{F}_1$ that corresponds to the homotopy of (1). It is also PSPACE-complete to find the coordinates of an approximate fixpoint of $\mathcal{F}_1$ that would be obtained by following a sequence of approximate fixpoints of $\mathcal{F}_1$ in which consecutive points are within distance $\alpha$ of each other.

Proof: We reduce from the problem defined in Proposition 1 as follows. Let $B$ be a Brouwer-mapping circuit derived from OEOTL-instance $(S, P)$ using Proposition 1 and let $\mathcal{F}_B: K^{(n)} \rightarrow \{0, 1, 2, 3\}$ be the function computed by $B$. Let $\mathcal{F}_1: K \rightarrow K$ be the function computed by a linear arithmetic circuit that implements $\mathcal{F}_B$, and $\mathcal{F}_0$ be computed by a circuit that implements the basic bmf $f_0$ (where both implementations apply Theorem 2). $\mathcal{F}_1$ is given by (1).

Let $P$ be a connected subset of $K \times [0, 1]$ such that for any $(x, t) \in P$, $x$ is a fixpoint of $\mathcal{F}_0$, and $P$ contains $x_0 \in (K, 0)$ and $x_1 \in (K, 1)$. Browder’s fixpoint theorem (with Observation 2) assures us that such a $P$ exists. We claim that $x_1$ is within distance $2^{-n}$ of the unique solution to $B$ of the problem specified in Proposition 1 (and hence, given $x_1$ we can easily construct this solution).

Suppose otherwise. For $x_1$ to be a fixpoint (even an approximate one) of $\mathcal{F}_1$, by Observation 1 it must be within distance $2^{-n}$ of a panchromatic vertex $v$ of $f_B$. But now, $v$ is not connected to the origin via non-zero cubelets of $f_B$. By connectivity of $P$, there must exist $(x, t) \in P$ such that $x$ lies within a cubelet $K_x$ where $f_B(K_x) = 0$.

We may assume further that $x$ is at least $2^{-n}$ distant from any non-zero cubelet of $f_B$. This follows provided we assume that connected components of non-zero cubelets of $f_B$ are separated from each other by a layer of 0-colored cubelets of thickness at least 3. This may be safely assumed by increasing $n$ by a factor of 3 and subdividing the cubelets. We note that

1) each entry of vector $f_0(x) - x$ is $< -\alpha / 5$, and
2) each entry of $f_1(x) - x$ is $< -\alpha / 5$.

It follows that for $t \in [0, 1]$, each entry of $f(t(x) - x$ is less than $-\alpha / 5$, since coordinatewise, $f_0 \leq f_1 \leq f_B$. That means that $x$ cannot be an approximate fixpoint of any $f_t$, contradicting the assumption as required.

Since $x$ is at least $2^{-n}$ distant from any non-zero cubelet of $f_B$, it is also at least $2^{-n}$ distant from any non-zero cubelet of $f_0$, since for any cubelet $K_{ijk}$, $f_B(K_{ijk}) = 0 \implies f_0(K_{ijk}) = 0$. The implementation of any bmf $f$ as a function $\mathcal{F}$ computed by a linear arithmetic circuit, as referred to in Theorem 2, ensures that $\mathcal{F}(x) - x$ is a convex combination of vectors $\mathcal{F}(z) - z$ for cubelet centers $z$ in the vicinity of $x$, and since all those cubelet centers are colored 0, we have that the entries of $\mathcal{F}(x)$ are all less than $-\alpha / 5$, as required.

4. THE LINEAR TRACING PROCEDURE

We now turn to games and Nash equilibrium. Let $G$ denote an $n \times n$ game that we wish to solve, assumed to be chosen by an adversary. $G_0$ is a game with a unique “obvious” solution. In $G_0$ each player receives payoff 1 for his first action, and payoff 0 for all others, regardless of what the other player does.

In the problem LINEAR TRACING the solution consists of the Nash equilibrium of $G$ that is connected to the unique equilibrium $(s'_0, s'_0)$ of $G_0$ via equilibria of convex combinations $(1 - t)G_0 + tG$. We can also define an approximate version of this problem, where instances include an additional parameter $\epsilon$, and we seek an $\epsilon$-Nash equilibrium that is connected to the solution of $G_0$ via a sequence of $\epsilon$-approximate solutions of $G_t$. For the two-player case we assume $\epsilon = 0$. For more than 2 players, we need a positive $\epsilon$ to ensure that solutions can be written down as rational numbers.

Theorem 4: LINEAR TRACING is PSPACE-complete for 2-person games.

The same result then holds for strategic-form games with more than 2 players. It holds for a value of $\epsilon$ that is exponentially small; we could again use the ideas of [4] to obtain a version where $\epsilon$ is inverse polynomial.
4.1. Brief overview of the proof ideas

The following is a brief overview of the rest of this Section 4. Membership of PSPACE can be deduced from [13]. The reduction from the PSPACE-complete discrete Brouwer fixpoint problem of the previous section, applies the idea from [6] of going via graphical games to normal-form games. We derive a type of graphical game in which a specific player (denoted \( v_{\text{switch}} \)) acts as a switch, allowing the remaining players to simulate either the basic Brouwer-mapping function, or one associated with an instance of the search for a discrete Brouwer fixpoint. \( v_{\text{switch}} \) governs this behavior via his choice of either one of two alternative strategies, and we show that a continuous path of equilibria from one choice to the other, results in an equilibrium that ultimately represents a solution to OEOIL. The graphical game is then encoded as a 2-player game such that the linear-tracing procedure corresponds to this continuous path of equilibria in the graphical game.

4.2. Graphical Games

In a graphical game [17], each player is a vertex of a graph, and his payoffs depend on his own and his neighbors’ actions. For a low-degree graph, this is one way that games having many players may be represented concisely. A homotopy between two graphical games \( \mathcal{G}_0 \) and \( \mathcal{G}_1 \) would require that these games have the same underlying graph, so that they differ only in their numerical payoffs. In the graphical games considered here, each player has just 2 actions and 3 neighbors. The main result of this section is

Proposition 3: Consider graphical games that contain a special player \( v_{\text{switch}} \) whose payoffs are constant (unaffected by his own actions or the other players’). The following problem is PSPACE-complete: find a Nash equilibrium of the game where \( v_{\text{switch}} \) plays 1, that is topologically connected to a Nash equilibrium in which \( v_{\text{switch}} \) plays 0, via a path of Nash equilibria in which \( v_{\text{switch}} \) plays mixed strategies.

Let \( F_0 \) and \( F_1 \) be functions computed by linear arithmetic circuits that implement Brouwer-mapping functions \( f_0 \) and \( f_1 \), where \( f_0 \) is the “basic bmf” of Definition 2, and \( f_1 \) is a DGP-style bmf that encodes some instance of END OF THE LINE.

Note 3: In a graphical game in which all players have 2 pure strategies denoted 0 and 1, given a mixed-strategy profile for the players we let \( p[v] \) denote the probability that player \( v \) plays 1.

Definition 5: Given a bmf \( f \), we construct an associated graphical game \( \mathcal{G}_f \) as follows. \( \mathcal{G}_f \) has 3 special players \((v_x, v_y, v_z)\) whose strategies \((p[v_x], p[v_y], p[v_z])\) represent a point in \( K \). If \( f \) is implemented by \( F : K \rightarrow K \) we use gadgets of [6] to simulate the nodes in the arithmetic circuit that computes \( F \) (each node of the circuit is an additional associated player in \( \mathcal{G}_f \)). The game can pay them to adjust \((p[v_x], p[v_y], p[v_z])\) in the direction \( F(p[v_x], p[v_y], p[v_z]) - (p[v_x], p[v_y], p[v_z]) \). Then the players \((v_x, v_y, v_z)\) are incentivized to play \( F(p[v_x], p[v_y], p[v_z]) \). Consequently a Nash equilibrium of \( \mathcal{G}_f \) corresponds to a fixpoint of \( F \). Moreover, an \( \epsilon \)-Nash equilibrium corresponds to a poly(\( \epsilon \))-approximate fixpoint of \( F \). We call \( \mathcal{G}_f \) a linear graphical game since we only allow players whose payoffs cause them to simulate the gates of linear arithmetic circuits.

A game of the above kind is said to simulate \( f \). We say further that a game \( \mathcal{G} \) simulates a partial bmf on a subset \( S \) of cubelets, if for any \( K \in S \), when \((p[v_x], p[v_y], p[v_z])\) lie at the center of \( K \) the players \((v_x, v_y, v_z)\) are incentivized to play \((p[v_x], p[v_y], p[v_z]) + \delta_c\), where \( c = f(K) \).

Lemma 1: Given any linear graphical game \( \mathcal{G}_1 \) that simulates a Brouwer-mapping function \( f_1 \), we can efficiently construct a new game \( \mathcal{G}^+ \) having a player \( v_{\text{switch}} \) whose behavior can either cause \( \mathcal{G} \) to simulate \( f_1 \) (if \( v_{\text{switch}} \) plays 1) or cause \( \mathcal{G} \) to simulate \( f_0 \) if instead \( v_{\text{switch}} \) plays 0.

\( v_{\text{switch}} \) shall serve as a “switch”, in allowing the game to switch between simulating \( f_0 \) and \( f_1 \) (using an additional 3 players \((v_x^+, v_y^+, v_z^+)\) whose strategies represent a point in \( K \) according to whether \( v_{\text{switch}} \) plays 0 or 1. Of course, \( v_{\text{switch}} \) has a key role in the associated two-player game.

Proof: For \( i \in \{0, 1\} \), let \( \mathcal{G}_i \) be a graphical game constructed from \( f_i \) according to Definitions 2, 4, 5. \( \mathcal{G}_i \) has 3 players/vertices whose mixed strategies, as represented by the probabilities that they play 1, represent a point in \( K \). Denote these players \((v_x^+, v_y^+, v_z^+)\).

Construct a “combined” game \( \mathcal{G}^+ \) as follows. \( \mathcal{G}^+ \) contains all the players in \( \mathcal{G}_0 \) and \( \mathcal{G}_1 \) together with a new player \( v_{\text{switch}} \), whose behavior is governed by

\[
\begin{align*}
p[v_x^+] &= (p[v_x^0] - p[v_{\text{switch}}]) + (p[v_x^1]) - (1 - p[v_{\text{switch}}]) \\
p[v_y^+] &= \max(p[v_y^0], \min(p[v_y^1], p[v_{\text{switch}}]))
\end{align*}
\]

(same expressions for \( v_z^+ \) and \( v_y^+ \)) where the parentheses in the above expression are important since the outputs of the operators + and − are truncated to lie in \([0, 1]\).

Players from \( \mathcal{G}_0 \) and \( \mathcal{G}_1 \) that take input from nodes \( v_i^0 \) or \( v_i^1 \) respectively, are then modified to take that input from \( v_i^+ \) instead. This completes the construction.

Proof: of Proposition 3: We reduce from the circuit homotopy of Theorem 3. Let \( \{f_t : t \in [0, 1]\} \) be an instance of this circuit homotopy. Construct \( \mathcal{G} \) from \( F_1 \) as per Definition 5. Construct \( \mathcal{G}^+ \) as in Lemma 1, and we make the following observation:

Observation 3: Suppose that in \( \mathcal{G}^+ \) we have \( p[v_{\text{switch}}] = t \in (0, 1) \). The resulting game \( \mathcal{G}^+ \) simulates a partial Brouwer-mapping function \( f_t \) which is implemented by a Brouwer function \( F_1 \) that is (pointwise) a convex combination of \( F_0 \) and \( F_1 \) and is defined on the subset of cubelets where \( f_0 = f_1 \). Given a homotopy path of Nash equilibria of \( \mathcal{G}^+ \) that
start at the unique equilibrium of \( GG^+ \) that satisfies 
\[ p(v_{\text{switch}}) = 0 \] 
and ends at an equilibrium of \( GG^+ \) in which \( p(v_{\text{switch}}) = 1 \), there is a corresponding homotopy path from the fixpoint of \( F_0 \) and a fixpoint of \( F_1 \) (noting that (2) is essentially the same as (1)). That concludes the proof of Proposition 3.

The following version of Lemma 1 is useful in the construction for Lemke-Howson solutions, later on.

**Corollary 1:** Given any linear graphical game \( GG_1 \) that simulates a Brouwer-mapping function \( f_1 \), we can efficiently construct a new game \( GG^+ \) having 2 players \( v_{\text{switch}} \) and \( v'_{\text{switch}} \) whose behavior can either cause \( GG^+ \) to simulate \( f_1 \) (if both \( v_{\text{switch}}, v'_{\text{switch}} \) play 1) or cause \( GG^+ \) to simulate \( f_0 \) if instead either or both play 0.

### 4.3. From graphical to two-player strategic-form games

In this subsection we prove the following theorem, from which Theorem 4 follows.

**Theorem 5:** It is PSPACE-hard to compute the Nash equilibrium of a given 2-player normal-form game \( G_1 \), that is obtained via the linear homotopy that starts from \( G_0 \), a version of \( G_1 \) where the payoffs have been changed to give each player payoff 1 for his first strategy and 0 for the others.

We reduce from the graphical game problem of Proposition 3. Let \( GG^+ \) be a linear graphical game that includes a player \( v_{\text{switch}} \) as per Proposition 3. First, modify \( GG^+ \) to give \( v_{\text{switch}} \) a small payment (say, 0.01) to play 1, and zero to play 0.

We define a homotopy between two-player strategic-form games \( G_0 \) and \( G_1 \) such that equilibria of \( G_1 \) efficiently encode equilibria of \( GG^+ \), and equilibria of \( G_1 \) encode equilibria of versions of \( GG^+ \) where \( v_{\text{switch}} \) has a bias towards playing 0. We use the reduction of [6] (Section 6.1) from graphical games to 2-player games.

Given a mixed-strategy profile, let \( Pr[s] \) denote the probability allocated to pure strategy \( s \) by its player.

**Definition 6:** A circuit-encoding 2-player game \( G \) has a corresponding graphical game \( GG \) where the graph of \( G \) is bipartite; denote it \( G = (V_1 \cup V_2, E) \); each player (vertex) in \( GG \) has 2 actions (denote them 0 and 1) and payoffs that depend on the behavior of 2 other players in the opposite side of \( G \)'s bipartition. Each vertex/action pair \((v, a)\) of \( GG \) has a corresponding strategy in \( G \); for \( v \in V_1 \), \((v, a)\) belongs to the row player and for \( v \in V_2 \), \((v, a)\) belongs to the column player. The payoffs in \( G \) are designed to ensure that in a Nash equilibrium of \( G \)

- \( Pr[(v, 0)] + Pr[(v, 1)] = 1 \) where \( n \) is the number of players in \( GG \)
- if in \( GG \), \( v \) plays 1 with probability \( Pr[(v, 1)]/Pr[(v, 0)] + Pr[(v, 1)] \) then we have a Nash equilibrium of \( G \).

Let \( G \) be a circuit-encoding game derived from \( GG^+ \) according to Definition 6. Associate \( v_{\text{switch}} \) with 2 strategies of the column player of \( G \), and let \( s_k \) and \( s_{k+1} \) be these strategies. Hence a Nash equilibrium of \( G \) corresponds to one of \( GG^+ \) where the value \( p(v_{\text{switch}}) \) is given by the value \( Pr[s_{k+1}](Pr[s_k] + Pr[s_{k+1}]) \).

**Observation 4:** If we take a circuit-encoding 2-player game, and award one of the players a small bonus to play \((v, a)\), then this corresponds to incentivizing the player \( v \) in \( GG \) to select strategy \( a \). The corresponding incentive for \( v \) will be larger, but only polynomially larger.

Let \( G_0 \) be a \((n + 1) \times (n + 1)\) game with strategies \( \{s_0', \ldots, s_n'\} \) for the row player, and \( \{s_0, \ldots, s_n\} \) for the column player. Payoffs are as follows: each player receives 1 for playing \( s_0' \) or \( s_0 \), and 0 for \( s_j' \) or \( s_j \) for \( j > 0 \).

Rescale the payoffs of \( G \) to all lie in the range \([0, 0.5]\). Let \( G_1 \) be a \((n + 1) \times (n + 1)\) game with strategies \( \{s_0', \ldots, s_n'\} \) for the row player, and \( \{s_0, \ldots, s_n\} \) for the column player. Payoffs are as follows:

- \((s_0', s_0)\) results in payoffs \((0, -1)\) for the players.
- \((s_0', s_j')\) for \( j > 0 \) results in payoffs \((0, 0.5)\).
- \((s_j', s_0)\) for \( j > 0 \) results in payoffs \((-1, 0.5)\) for \( j \neq k \), and \((-1, 0.5 + \delta)\) (for \( \delta \) inverse polynomial in \( n \)) for \( j = k \).
- The rest of \( G_1 \) is a copy of \( G \) above.

Let \( G_t = (1 - t)G_0 + G_1 \). The above payoffs have been chosen so that Nash equilibria satisfy: in \( G_1 \), players do not use \( s_0' \) or \( s_0 \), and in \( G_0, s_0 \), players both have a proper mixture of \( s_0' \) and \( s_0 \) with their other strategies. Since \( G_1 \)’s payoffs were rescaled to lie in \([0, 0.5, 1, 1, 0.5] \), \( Pr[s_0'] \) and \( Pr[s_0] \) can be shown to lie in \([0, 0.5, 0, 0, 0, 0] \), which can be checked from the following payoff ranges for \( G_0, G_1 \):

<table>
<thead>
<tr>
<th>( s_0' )</th>
<th>( s_0 )</th>
</tr>
</thead>
<tbody>
<tr>
<td>( (0, 0.5, 0, 0, 0, 0) )</td>
<td>( (0, 0.5, 0, 0, 0, 0) )</td>
</tr>
<tr>
<td>( s_0' )</td>
<td>( s_0 )</td>
</tr>
<tr>
<td>( (0.04, 0.04, 0.04, 0.04, 0.04) )</td>
<td>( (0.04, 0.04, 0.04, 0.04, 0.04) )</td>
</tr>
</tbody>
</table>

Thus a continuous path of equilibria should at some stage allocate gradually less and less probability to \( s_0 \) and \( s_0' \) as \( t \) increases.

**Observation 5:** In any Nash equilibrium \( N \) of \( G_1 \), the players assign probability \( 0 \) to \( s_0' \) and \( s_0 \), and consequently \( N \) consists of a Nash equilibrium of \( G \), restricting to strategies \( s_j' \) and \( s_j \) for \( j, j' > 0 \).

Since \( G_t = (1 - t)G_0 + G_1 \), we can write \( G_t \) as:

\[
\begin{array}{cccccc}
& s_0 & s_1' & \ldots & s_{k-1}' & s_k & s_{k+1}' & \ldots & s_n' \\
\hline
s_0' & (1 - t, 1 - 2t, & (1 - t, 2t) & (1 - t, t) & (1 - t, \frac{t}{4}) & (1 - t, \frac{t}{4}) & \ldots & (1 - t, \frac{t}{4}) \\
& (-t - 1, \frac{t}{4}) & (-t, \frac{t}{2}) & (-t, \frac{t}{4}) & (-t, \frac{t}{4}) & \ldots & (-t, \frac{t}{4}) \\
& \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\
& s_n' & (-t, 1) & (-t, 1) & (-t, 1) & \ldots & \ldots & \ldots & \ldots \\
\end{array}
\]

The general idea is as follows. Consider the Browder path of equilibria that begins from the unique equilibrium of \( G_0 \) (where initially both players play \( s_0', s_0 \)). As \( t \) increases, the players will start to use the other strategies. At that stage, consider the distribution of their mixed strategies restricted to \( s_1', \ldots, s_n' \) and \( s_1, \ldots, s_n \). These distributions will constitute a Nash equilibrium of a version of \( G \) in which the column player receives a small bonus for playing \( s_k' \). As \( t \) increases to 1, the bonus decreases continuously to 0, and we recover.

Footnote 2: The two-component payoff vectors assign the first component to the row player and the second component to the column player.
Observation 5. Now, recall from Definition 6 that the way \([6, 4]\) reduce graphical games to two-player games, is to associate each player \(v\) in the graphical game with two strategies in the two-player game, both belonging to the same player. The division of probability between those two strategies represents the probability that \(v\) plays \(1\). Consider \(v_{\text{switch}}\) now, corresponding to \(s^e_v\) and \(s^f_v\) \(v_{\text{switch}}\) is, in the graphical game, mildly incentivized to play \(1\), but for \(t < 1\) the \(\delta\) in the two-player game \(G_t\) pushes it the other way, towards \(0\). As a result, a Nash equilibrium of \(G_t\) may simulate a Nash equilibrium of \(GG_t^v\) where \(p[v_{\text{switch}}] \in (0, 1)\). As \(t\) increases and the contribution from \(\delta\) decreases, this process corresponds to raising \(p[v_{\text{switch}}]\) continuously (but not monotonically) from \(0\) to \(1\).

**Lemma 2**: Let \(N\) be a Nash equilibrium of \(G_t\) in which \(\Pr[s^0_r] < 1\) and \(\Pr[s^0_r] < 1\). Let \(P\) be the probability distributions over \(\{s^r_1, \ldots, s^r_n\}\) and \(\{s^c_1, \ldots, s^c_n\}\) obtained by taking each value \(\Pr[s^r_i]\) for \((i \in \{r, c\}, 1 \leq j \leq n)\) and dividing it by \(1 - \Pr[s^0_r]\).

Then \(P\) is a Nash equilibrium of a version of \(G\) where the column player receives a bonus of \(\delta \Pr[s^r_1]/(1 - \Pr[s^r_1])\) for \(s^r_c\).

**Proof**: In Nash equilibrium \(N\), \(c\)'s strategy \(s^e_c\) contributes the same quantity to each one of \(r\)'s strategies \(s^r_1, \ldots, s^r_n\). So the values \(\Pr[s^r_1], \ldots, \Pr[s^r_n]\) must form a best response to \(c\)'s mixed strategy from \(P\).

The column player receives a bonus \(\delta \Pr[s^r_1]\) specific to \(s^r_c\), arising from the possibility that row player plays \(0\). He also receives an additional \(\frac{2}{t}\) for all strategies \(s^r_j\) for \(j > 0\), but that uniform bonus has no further effect on his preference amongst \(s^r_1, \ldots, s^r_n\).

So in \(N\), \(\Pr[s^r_1], \ldots, \Pr[s^r_n]\) is a best response to a mixture of \(G\) weighted by \(1 - \Pr[s^0_r]\) and the probability \(\Pr[s^0_r]\) of a bonus \(\delta \Pr[s^r_1]\) for playing \(s^r_c\). This is equivalent to a best response to a version of \(G\) with a bonus of \(\delta \Pr[s^r_1]/(1 - \Pr[s^r_1])\) for \(s^r_c\). □

Consider the path of equilibrium connecting equilibrium \(N_0\) of \(G_0\) to equilibrium \(N_1\) of \(G_1\). By Lemma 2 we can choose \(\delta\) such that in any equilibrium of \(G_0\), we have \(\Pr[s^k_1] = 0\). We also have that in any equilibrium of \(G_1\), \(\Pr[s^0_1] = 0\). Consider the longest suffix of the path for which \(t \geq 0.5\) for all games \(G_t\) that appear in that suffix. The corresponding equilibrium assign weight strictly less than \(1\) to \(s^r_1\) and \(s^0_1\), so Lemma 2 may be used to recover corresponding equilibrium of versions of \(G\) in which turn correspond to versions of \(GG_t^v\) in which initially, \(v_{\text{switch}}\) is incentivized to play \(0\), and finally, \(v_{\text{switch}}\) is incentivized to play \(1\).

5. **FROM LINEAR TRACING TO THE HOMOTOPIES OF VAN DEN ELZEN-TALMAN, HERINGS-VAN DEN ELZEN, AND HERINGS-PEETERS**

In the previous section, we showed the PSPACE-completeness of finding the Nash equilibrium of a two-player game that is associated with a homotopy that uses a specific simple starting-game that is not derived from the game of interest. In the literature on homotopy methods, starting with Harsanyi [10], the starting-game is usually derived from the game of interest by positing a prior distribution over the players’ pure strategies, and using a starting-game whose payoffs are the result of playing against this prior distribution. In this section, we extend the result of Section 4 to handle these starting-games and thus obtain results for the Herings-van den Elzen [13] and Herings-Peeters [14] algorithms, which use the same underlying homotopy, and the van den Elzen-Talman [15] algorithm, which uses a different homotopy. All three algorithms have been shown under certain conditions to mimic the Harsanyi-Selten linear tracing procedure. For each algorithm, we use the uniform distribution as the prior distribution, which is a natural choice.

The van den Elzen-Talman algorithm uses a homotopy based on a starting mixed-strategy profile \(v\). Letting \(\Sigma\) be the set of mixed-strategy profiles, let \(\Sigma(t)\) be the set of convex combinations \((1-t)p + t\Sigma\). In the notation of [15], the van den Elzen-Talman algorithm — restricted to the two-player case — uses the homotopy

\[
H(t, \sigma) = \beta^2_1(t) \times \beta^2_2(t) \sigma
\]

where \(i = 1, 2\), \(\beta^2_i(t)\) denotes the best responses of player \(i\) to mixed strategy \(\sigma\), restricted to \(\Sigma(t)\).

**Theorem 6**: It is PSPACE-complete to compute equilibria that result from the above van den Elzen-Talman homotopy.

The proof works by giving each player a dummy strategy which does not get used in any equilibrium, but whose payoffs ensure that the uniform distribution (at \(t = 0\)) over all players’ strategies results in payoffs that looks like \(G_0\). A similar trick works for the homotopy of [13, 14].

6. **FROM LINEAR TRACING TO LEMKE-HOWSON**

The Lemke-Howson (L-H) algorithm is an important and rich research subject in and by itself within Game Theory; for the purposes of this reduction, it is helpful to take a point of view that considers the L-H algorithm as a homotopy [15], where an arbitrary strategy (the one whose label is dropped initially) is given a large “bonus” to be played, so that the unique equilibrium consists of that strategy together with its best response from the other player; the homotopy arises from reducing that bonus continuously to zero.

**Theorem 7**: It is PSPACE-complete to find any of the solutions of a 2-player game that are constructed by the Lemke-Howson algorithm.

The remainder of this section proves Theorem 7, the hardness being established by a reduction from the graphical game problem of Proposition 3, extending the ideas of the reduction for LINEAR TRACING (Theorems 4, 5). A new technical challenge here is that the choice of initially dropped label results in \(2n\) alternative homotopy paths, and we must ensure that any of the (up to) \(2n\) solution can encode the single solution to some instance of LINEAR TRACING.

Suppose that some strategy has been given this “L-H bonus”, and a Browder path of Nash equilibrium is obtained from reducing that bonus to zero. As before
let \( t \in [0, 1] \) be a parameter that denotes the distance from the starting game of the homotopy to the game of interest, so that \( 1 - t \) is a multiplicative weight for the bonus in intermediate games. Consider the Browder path. It is piecewise linear, a topologically well-behaved line. Let \( T \in [0, 1] \) parameterize points along the Browder path — an equilibrium \( \mathcal{N}_T \) is the one that is a fraction \( T \) of the distance along the path (starting at the version of the game with the L-H bonus). So, multiple values of \( T \) can correspond to the same value of \( t \). Here we mostly focus on \( T \) rather than \( t \).

The following construction addresses the issue that an arbitrary strategy may receive the L-H bonus. We embed two copies of a circuit-encoding game \( \mathcal{G} \) (Definition 6) into a game instance for the Lemke-Howson algorithm. At least one of those copies of \( \mathcal{G} \) will not contain the strategy that receives the L-H bonus. The L-H homotopy, restricted to that copy of \( \mathcal{G} \), will simulate the homotopy of Section 4.

In Figure 1, \( \mathcal{G} \) denotes a circuit-encoding \( n \times n \) game (note the two copies whose payoffs have been rescaled to lie in the interval [0, 4, 0, 6]), \( \mathcal{G} \) is assumed to have an associated graphical game with two “switch” players \( v_{s_{\text{switch}}}^\text{row}, v_{s_{\text{switch}}}^\text{col} \), that affect the equilibria of \( \mathcal{G} \) according to Corollary 1. They will correspond to the first pair of each of \( \mathcal{G} \)’s players’ strategies \((s_0^r, s_1^r)\) and \((s_0^c, s_1^c)\) such that:

- if both \( p[v_{s_{\text{switch}}}^\text{row}] = 1 \) and \( p[v_{s_{\text{switch}}}^\text{col}] = 1 \), \( \mathcal{G} \)’s equilibrium encodes a solution to an END OF THE LINE instance that is efficiently encoded by \( \mathcal{G} \); if either \( p[v_{s_{\text{switch}}}^\text{row}] = 0 \) or \( p[v_{s_{\text{switch}}}^\text{col}] = 0 \), \( \mathcal{G} \) encodes the “basic” Browder-mapping function;
- if we add a bonus to the row player for his first strategy \( s_0^r \) that is less than some threshold \( \tau \), it will result in \( \Pr[s_0^r] = 0 \) and hence \( p[v_{s_{\text{switch}}}^\text{row}] = 1 \), and similarly for the column player with respect to \( s_0^c \) and \( v_{s_{\text{switch}}}^\text{col} \). (We will see that such bonuses occur, and they decrease at \( T \to 1 \).)

**Notation.** \( A, B, C, D \) and \( A', B', C', D' \) denote sets of the players’ strategies as shown in Figure 1. In the context of a mixed-strategy profile, \( \Pr[A] \) denotes the probability that the column player uses \( C \); \( \Pr[D] \) that he chooses an element of \( A \), and so on. Let \( X(T) = \Pr[C] + \Pr[D] + \Pr[C'] + \Pr[D'] \), a function of distance along the Browder path. We note the following facts:

- \( X(0) \geq 1 \) (if, say, a column player strategy receives the L-H bonus, then the row player will play some pure best response, either \( C' \) or \( D' \); so \( \Pr[C'] = 1 \) or \( \Pr[D'] = 1 \)).
- \( X(1) \leq \frac{1}{\tau_0} \) (shown in Lemma 4) together with the key observation that \( X(T) \) is a continuous function of \( T \), implying:

**Observation 6:** For some \( T' \in [0, 1] \), \( X(T') = \frac{1}{4} \), and for \( T > T' \), \( X(T) < \frac{1}{4} \).

Let \( \bar{\mathcal{G}} \) be the copy of \( \mathcal{G} \) that does not contain the strategy that receives the L-H bonus. (If one of \( C, D, C' \) or \( D' \) receive the L-H bonus, then \( \bar{\mathcal{G}} \) may be either copy of \( \mathcal{G} \).)

For any \( X \), at least one player \( p \) has an additional bonus at least \( X/4 \) to play \( s_0^p \) in \( \bar{\mathcal{G}} \) (suppose for example \( \Pr[C] + \Pr[D] \geq X/2 \) and \( p \) is the row player; Figure 1 awards additional \( e = 1 \) to \( p \) when \( C \) or \( D \) is played). But neither player’s bonus exceeds \( X/2 \). As \( T \) increases from \( T' \) to 1, \( X(T) \) goes down from \( \frac{1}{4} \) to at most \( \frac{1}{6} \).

We establish that when \( X(T) = \frac{1}{T} \), \( \mathcal{N}_T \) contains a solution to a “biased” version of \( \mathcal{G} \) where one of the players’ first strategies (i.e. \( s_0^r \) or \( s_0^c \)) has an additional bonus (enough to ensure \( \Pr[s_0^r] = 0 \) and \( p[v_{s_{\text{switch}}}^\text{row}] = 0 \), in the case of the row player). Furthermore, when \( T = 1 \), we have that \( \mathcal{N}_T \) contains a solution to \( \mathcal{G} \), only with smaller biases. These biases are associated with “switch” strategies in the graphical game associated with \( \mathcal{G} \).

Let \( T' \) be the largest value of \( T \) where \( X(T) \) is large enough that one of the bonuses sets \( \Pr[s_0^p] = 1 \) in \( \bar{\mathcal{G}} \) (for \( p \in \{r, c\} \)). Between \( T' \) and \( T = 1 \) we pass through a continuum of equilibria where \( \Pr[s_0^p] \) changes from 1 to 0; equivalently \( p[v_{s_{\text{switch}}}^\text{row}] \) changes from 0 to 1, and the resulting equilibrium at \( T = 1 \) corresponds to a solution to \( \text{OEOTL} \).

**Lemma 3:** Let \( \mathcal{N}_T \) be a solution of \( \mathcal{G}_T \). If \( \mathcal{G} \) is the bottom right-hand copy of \( \mathcal{G} \) in Figure 1, then if the distributions over \( B \) and \( B' \) are normalised to 1, we have a Nash equilibrium of a game \( \mathcal{G} \) where the row player has an additional bonus of \( e(\Pr[C] + \Pr[D]) / \Pr[B'] \) to play his first strategy \( s_0^r \), and the column player has an additional bonus of \( e(\Pr[C'] + \Pr[D']) / \Pr[B] \) to play his first strategy \( s_0^c \).

By symmetry, a similar result also holds in the case that \( \mathcal{G} \) is the top right-hand copy of the \( \mathcal{G} \).

**Proof:** Payoffs to the row player are unaffected by the column player’s distribution over \( A \). Meanwhile, \( C \) and \( D \) lead to an additional bonus of \( e \) (weighted by the probability that \( C \) and \( D \) are used by the column player) for the row player to use the top row of \( B' \).

**Lemma 4:** At \( t = 1 \) (equivalently, \( T = 1 \)) we have in any Nash equilibrium, that \( \Pr[C] \leq \frac{1}{17} \), \( \Pr[D] \leq \frac{1}{17} \), \( \Pr[C'] \leq \frac{1}{17} \) and \( \Pr[D'] \leq \frac{1}{17} \). Since \( M \geq 100 \) we have \( X(1) \leq \frac{1}{125} \).

A proof of Lemma 4 may be found in the full version.

**Lemma 5:** Assume that \( e \leq 1 \) in Figure 1 and that \( M \geq 100 \). Suppose that \( X(T) \leq \frac{1}{4} \). Then \( \Pr[A] \geq \frac{1}{17} \), \( \Pr[B] \geq \frac{1}{17} \), \( \Pr[A'] \geq \frac{1}{17} \), \( \Pr[B'] \geq \frac{1}{17} \).

A proof of Lemma 5 may be found in the full version. At \( X(T) = \frac{1}{4} \) we have that at least one of \( \Pr[C], \Pr[D], \Pr[C'], \Pr[D'] \) is at least \( \frac{1}{17} \), while at the end of the Browder path, we know that all these quantities are at most \( \frac{1}{17} \). We set the switch threshold probability to be somewhere between these, but we have to use lower bounds on \( \Pr[A], \Pr[B], \Pr[A'], \Pr[B'] \) at \( t = 1 \) and upper bounds on these at \( X = \frac{1}{4} \) (as well as lower bounds on these at \( X = \frac{1}{4} \) to ensure that a Nash equilibrium of the “biased game” is being encoded).

Finally, we need to show that there exists \( \tau \) such that the bonus from at least one switch strategy in \( \bar{\mathcal{G}} \) changes continuously above \( \tau \) to below it, while the bonus for the other switch strategy ends up below \( \tau \), thus initially,
at least one value of $p[v]_{\text{switch}}^r$ and $p[v]_{\text{switch}}^c$ is zero, but at the end both evaluate to 1. This needs to take into account the variable amount of probability allocated to the strategies in $G$, since that affects the impact of the bonuses on $s_0^p$.

For any $T \in [T', 1]$ the weight assigned by each player to $G$'s strategies is at least $\tau_1$ by Lemma 5, so that the bonus for player $p$ to play $s_0^p$, falls by a larger factor than the probability that $G$ is played. That means that $\tau$ can indeed be chosen as required.

7. DISCUSSION AND OPEN PROBLEMS

Should a more general result be obtainable? For example, perhaps it should be possible to identify general classes of “path-following algorithms” that include the ones we analyzed here, for which it is PSPACE-complete to compute their output.
